Superconductivity in optimally doped cuprates: BZA program works well and superexchange is the glue

(Received 9 September 2006; accepted 10 October 2006)

Abstract
Resonating valence bond states in a doped Mott insulator was proposed to explain superconductivity in cuprates in January 1987 by Anderson. A challenging task then was proving existence of this unconventional mechanism and a wealth of possibilities, with a rigor acceptable in standard condensed matter physics, in a microscopic theory and develop suitable many body techniques. Shortly, a paper by Anderson, Zou and us (BZA) undertook this task and initiated a program. Three key papers that followed, shortly, essentially completed the program, as far as superconductivity is concerned: i) a gauge theory approach by Anderson and us, that went beyond mean field theory ii) Kotliar’s d-wave solution in BZA theory iii) improvement of a renormalized Hamiltonian in BZA theory, using a Gutzwiller approximation by Zhang, Gros, Rice and Shiba. In this article I shall focus on the merits of BZA and gauge theory papers. They turned out to be a foundation for subsequent developments dealing with more aspects that were unconventional - d-wave order parameter with nodal Bogoliubov quasi particles, Affleck-Marston’s $\pi$-flux condensed spin liquid phase, unconventional spin-1 collective mode at $(\pi, \pi)$, and other fascinating developments. Kivelson, Rokhsar and Sethna’s idea of holons and their bose condensation found expression in the slave boson formalism and lead to results similar to BZA program. At optimal doping, correlated electrons acquire sufficient fermi sea character, at the same time retain enough superexchange inherited from a Mott insulator parentage, ending in a BCS like situation with superexchange as a glue! Not surprisingly, mean field theory works well at optimal doping, even quantitatively. Further, $t$-$J$ model is a minimal model only around optimal doping, where RVB superconductivity is also at its best.

Keywords: high temperature superconductivity, Mott insulator, Hubard model, RVB theory

1. Introduction
Discovery of high $T_c$ superconductivity in cuprates by Bednorz and Müller [1] in 1986 is a remarkable event. It was a breakthrough and a major turning point in the history of superconductivity and strongly correlated electron systems. The field of quantum condensed matter physics and the community even got reorganized. About a month after Tanaka and collaborators confirmed [2] and brought to light Bednorz-Müller’s path breaking discovery, Anderson (PWA) [3] proposed a theory for high- $T_c$ superconductivity. We followed it up with several papers [4-9], focusing on superconductivity, within a span of one year. Several groups joined hands resulting in a flood of activities.

Anderson’s paper, to be referred to as PWA[3], which suggested the resonating valence bond (RVB) mechanism of superconductivity, was very appealing and at the same time very unconventional. A challenge then was, as a first step, i) theoretically establishing RVB mechanism of superconductivity, in the t-J model and ii) develop a suitable many body theory that will be useful to calculate a variety of physical quantities and also confirm several of the predictions of PWA. This task was executed in two papers, in quick succession, by Anderson Zou and us (BZA)[4] and Anderson and us (BA)[5]. During this period, except for a large value of superconducting $T_c$, not much was known experimentally, including fundamental properties such as, number of bands crossing the fermi level, symmetry of superconducting order parameter and survival of superexchange interaction in the doped Mott insulator. It is in this background, these two papers provided a proof, acceptable in standard condensed matter physics, of the unconventional phenomena of RVB superconductivity in a doped Mott insulator, and a theoretical frame work, a program, that became foundational for further quantitative developments. This was the beginning of the BZA program.

The richness of Anderson’s suggestion was that superconductivity in cuprates has turned out to be unconventional in more than one way: i) a new electronic mechanism, in an unexpected place called a doped Mott insulator and associated large $T_c$, ii) preformed spin pairing, later called ‘spin gap’ phenomenon, an unusual precursor to superconductivity,
over a wide temperature region above \( T_c \), iii) unconventional \( d \)-wave order parameter with nodal quasi particles, iv) unconventional spin-1 collective mode at \((\pi, \pi)\) and v) an unusual competition from other types of charge and spin orderings etc.

Superconductivity in cuprate family is a robust phenomenon at optimal doping. It has overcome disorder, charge and spin order tendencies and lattice instabilities. At optimal doping it is present in all cuprates containing \( \text{CuO}_2 \) layers. A large condensation energy is evident in the way superconducting \( T_c \), at optimal doping, jumped from the range of 30 to 90 to 120 and then 160 Kelvin, in new members of the cuprate family. A record \( T_c \sim 163 \text{K} \) is being held by a Ti based cuprate under a large external pressure. As RVB theory was based on spins and their exchange interactions, it was able to account for the large transition temperature and large condensation energies in a natural fashion, compared to attempts based on phonon and other mechanisms. A strength of RVB theory from the beginning was its sound phenomenological basis, from where a flow of new concepts was natural. Mathematical difficulties that followed were in the nature of strongly correlated electrons in a tight binding band; a suitable many body theory did not exist. Interestingly, these formidable mathematical difficulties were also overcome, very efficiently, in the theoretical developments that quickly followed.

There have been efforts, before Bednorz-Müller’s discovery, in discussing possibility of superconductivity in models containing repulsive interactions, to understand superconductivity in heavy fermions and organics. Historically, Hirsch [10] was the first to suggest an extended-s pairing in a repulsive Hubbard model. In a subsequent paper Scalapino, Loh and Hirsch [11] interpreted the same superconductivity as spin fluctuation mediated pairing. Other authors have used the idea of \( d \)-wave pairing mediated by spin fluctuations in nearly antiferromagnetic metals, such as heavy fermions [12] and Bechgard salts [13]. The idea of pairing due to spin fluctuations continue to be pursued for high \( T_c \) cuprates by several groups [14, 15]. One of the aims of the present paper is to bring out, as that superexchange rather than exchange of spin fluctuations is a natural, physically correct and mathematically straightforward method to describe the glue for cuprates. *Mott insulator is the template and superexchange is the glue.*

There has been a variety of efforts with varying success, in studying directly t-J and Hubbard models in 2D, for superconductivity, along the RVB route: Kivelson, Rokhsar and Sethna’s idea [16] of soliton doping and Bose condensation of holons, detailed slave boson analysis [7, 17, 18], detailed work [19] that sharpened the BZA phase diagram, an improved renormalized Hamiltonian analysis [20], gauge theory approaches [21-33], variational monte-carlo [34], quantum monte carlo [35], k-space [36] and real space [37] cluster DMFT methods, diagrammatics [38, 39] powerful renormalization group studies of Hubbard model in 2D [40, 41], exact diagonalization [42-44], series expansion [45, 46] and some analytical [47] methods have been employed.

In the following sections, we elaborate a view that the basic and important problem of establishing an electronic mechanism of superconductivity by a many body theory and key physics of Mott insulators, during 1987, was solved in the very first phase. Anderson has expressed this view [48, 49] in a recent article. The present article echoes similar views from a slightly different perspective giving some details. It has bit of history, as we will be completing 20 years since Bednorz-Müller’s path breaking discovery.

There is a recent review article by Lee, Nagaosa and Wen [33], which discusses physics of high \( T_c \) superconductivity in doped Mott insulators. It touches many of the theoretical developments. Our focus is on the BZA program, which has been so far very successful and has the potential to be used extensively for further quantitative progress. We also give some new insights and discussions.

In the concluding section we contrast and distinguish, theory of superconductivity in elemental metals from cuprates and other potential RVB superconductors. Even the type of questions raised and the way one addresses issues are different. The scientific efforts put in unraveling the mystery of the complex cuprate system does not have many parallel in condensed matter physics. At the end, it is fair to say we do understand a lot, to be able to say where superconductivity comes from and what is the mechanism. There is more to be understood, of course. Such a realization has two effects: i) some what loose statement one hears occasionally, ‘even now we do not understand high \( T_c \) superconductivity and the mechanism remains still unclear’, looses its validity and ii) it gives one confidence and suggests that RVB theory is well and the BZA program is ready to answer new and old questions from experiments. Some encouraging recent examples from theory are: i) variational Monte Carlo analysis of Gutzwiller projected RVB wave functions by Nandini, Paramekanti and Randeria [34], and finding a good agreement with results of the BZA program as well as some experimental results ii) detailed calculation of electronic structure properties and excited state properties by Gros-Muthukumar group [50], Ogata’s group [51] Zhang’s group [52] and others and iii) Anderson’s very recent attempt [49] to describe superconductivity and spin gap phenomena in an unified fashion using a notion of spin-charge locking and two types of Anderson-Nambu spinors.

**2. Brief introduction to a trio**

RVB proposal [3] in January 1987 created a spontaneous involvement of theorists and experimentalists from all over the world, from widely different background. The idea flourished instantly. Many key developments took place during 1987-88. For example, Kivelson, Rokhsar and Sethna’s idea [16] of soliton doping and Bose condensation of holons, spin-
charge decoupling, Kotliar’s $d$-wave solution [17], Zou-
Anderson’s slave boson formalism [7] adapted to t-J
model, Affleck-Marston’s phase [21], a condensate of $\pi$
-flux of RVB gauge field, enlargement of U(1) to SU(2)
RVB gauge theory [53], Zhang-Rice singlet construction
[54], an improvement of the renormalized Hamiltonian
used in BZA theory [20], sharpening of BZA phase
diagram by detailed slave boson studies [18, 19],
statistics transmutation [55], Laughlin’s idea [56] of
semin superconductivity (condensation of holons
carrying an RVB gauge field flux of $\pi/2$, other PT
violating chiral RVB states [57] Chern-Simons gauge
fields, computation of physical quantities using RVB
gauge field theory, anomalous normal state, failure of
fermi liquid theory, electron confinement, interlayer pair
tunneling and more. Some of them that are directly
related to one layer superconductivity are shown in
figure 1.
These intense activities revolved around PWA, BZA
and BA papers. We call these ‘trio’, as these three papers
have a close link and continuity. The RVB
superconducting state and related theoretical
developments in the trio in 1987 is similar to a BCS
type of theory, but based on electron correlation mechanism,
with its own novel features and notions and some
formidable theoretical problems. This is shown in Table
1. After phonon pairing mechanism and BCS theory,
RVB theory is the most significant development in the
field of superconductivity, involving an entirely different
mechanism based on electron correlations and more
importantly compelled by a rich phenomenology. Even
though heavy fermion superconductors and organic
superconductors existed around 1987, with an electronic
mechanism at work, it did not excite the condensed
matter community as much as cuprates did.

3. Anderson’s proposal
A qualitative and quantitative understanding of high $T_c$
superconductivity in cuprates involved, first identifying
the predominant mechanism of superconductivity. This,
in turn, involved three major steps: i) abstracting key
notions and introducing a new paradigm, ii) identifying
the right low energy effective Hamiltonian and iii)
developing suitable theoretical methods and finding
approximate solutions. Finding a new paradigm,
abstracting new notions and a model for cuprate
superconductivity, using known phenomenology of
La$_2$CuO$_4$ and other magnetic oxides is a remarkable
chapter in condensed matter physics. As PWA has
expressed in an article [58] entitled ‘Magnetician’s
edge’, a detailed and in depth knowledge of quantum
magnetism (particularly in oxides) was essential. The
phenomena of cuprate superconductivity turned out to be
a meeting ground of quantum magnetism and
superconductivity. The spirit of the approach to this
complex quantum condensed matter problem is well
summarized in ‘Central dogma in high $T_c$
superconductivity’, a chapter in PWA’s book on high $T_c$
superconductivity [9].

Figure 1. Evolution of BZA program beginning with Anderson’s
proposal. Kivelson et al.’s bose condensation of holon is an
independent development that also contributed to BZA program
through slave boson approach.

PWA [3] identified the parent compound La$_2$CuO$_4$ as a
spin-1/2 Mott insulator, having one electron in a non-
degenerate orbital per copper atom. This as well as the
doped La$_{2-x}$Ba$_x$CuO$_4$ is described by a single band large
U Hubbard model in 2D at and away from half filling:
\[
H = -\sum_{\langle ij \rangle} t_{ij} c_{i\sigma}^\dagger c_{j\sigma} + \sum_i n_{i\uparrow} n_{i\downarrow} \quad (1)
\]
Here the site index refers to a Wannier orbital. It is a
symmetry adapted hybrid of Cu 3d$^9$ - $\chi^\dagger$ and oxygen
2p orbitals, that retains $d_\chi$ - $\chi^\dagger$ symmetry. At half
filling and when $U \gg t$, the ground state is a Mott
insulator. It has a finite Mott Hubbard gap for charge
carrying excitations. Various estimates of U and t
and also next nearest neighbor hopping’s exist now: $U \sim 5$
$\text{eV}$, $t \sim 0.25 \text{eV}$. The ground state of the Hubbard model
at half filling is well approximated by the ground state
for hopping matrix element $t = 0$:
\[
|\sigma_1, \sigma_2, \ldots, \sigma_N\rangle \sim \prod_{i=1}^{N} c_{i\sigma}^\dagger |0\rangle \quad (2)
\]
In these states, every site is singly occupied and has a
dangling spin. Consequently, total spin degeneracy of
this manifold is $2^N$. The extensive spin entropy of the
above states are removed by superexchange, a second
order hopping processes, involving two neighboring sites
at a time. By a second order perturbation procedure we
can derive an effective Hamiltonian that lifts the $2^N$
fold spin degeneracy. For a given pair of neighboring sites,
the ground states for hopping, $t = 0$, are:
\[
|\uparrow, \uparrow\rangle, |\downarrow, \uparrow\rangle, |\uparrow, \downarrow\rangle, |\downarrow, \downarrow\rangle.
\]
These $2^2$ neutral spin configurations are three bond
triplets and a bond singlet state of two spins of

neighboring sites. When hopping t is introduced perturbatively, there is a virtual transition or mixing of the above states with the excited ‘ionic spin singlet’ intermediate configurations:
\[
| \uparrow \downarrow, 0 \rangle \text{ and } | 0, \uparrow \downarrow \rangle,
\]
resulting in a bond singlet ground state and bond triplet excited state. This is represented by the following effective Hamiltonian for the spin dynamics of the large U repulsive Hubbard model:
\[
H(\text{half filling}) - H_s = J \sum_{\langle ij \rangle} (S_i \cdot S_j - \frac{1}{4}),
\]
where \( J = \frac{U}{N} \).

PWA suggested that superexchange survives in the doped Mott insulators, up to some reasonable dopings. Electrons delocalize, but continue to respect the double occupancy constraint. The resulting model for non-half filled case is t-J model that contains in addition to the superexchange term \( H_s \) also the kinetic energy term \( H_t \):
\[
H_{tJ} = H_s + H_t = \sum_{\langle ij \rangle} \left( t \sum_{\sigma} c^\dagger_{i\sigma} c_{j\sigma} + h.c. + J \sum_{\langle ij \rangle} (S_i \cdot S_j - \frac{1}{4} n_i n_j) \right),
\]
with a double occupancy constraint, \( n_{i\uparrow} + n_{i\downarrow} \neq 2 \) at every site. Cuprates have a large superexchange \( J \sim 0.15 \) ev, one of the largest among spin-\( \frac{1}{2} \) Mott insulators.

PWA further suggested, in view of strong quantum fluctuations arising from spin-\( \frac{1}{2} \) character and 2 dimensionality, that ground state of this 2D Heisenberg model is a quantum spin liquid, with a possible pseudo fermi surface for certain neutral fermion excitations. The magnetic susceptibility data of Ganguly and Rao[59], for insulating \( \text{La}_2\text{CuO}_4 \), which did not exhibit any phase antiferromagnetic phase transition feature, also seemed to support PWA’s earlier notion of spin liquids[60] in 2D spin-\( \frac{1}{2} \) Heisenberg antiferromagnets.

Singlet correlations in this quantum spin liquid was suggested as the neutral singlets or preformed pairs that are waiting to superconduct, given an opportunity. On doping, a fraction \( x \) of neutral resonating singlets get charged resulting in superconductivity. Here \( x \) is the doping fraction. The RVB mechanism was expressed succinctly in the form of a Gutzwiller projected (double occupancy removed) BCS type wave function
\[
|RVB; \phi \rangle = P_G \prod_k (u_k + v_k c^\dagger_k c_k \phi (k) + |0 \rangle \langle 0 |)
\]
\[
= \prod_y \phi (y) b^\dagger_{y \uparrow} b_{y \downarrow}^{\phi (y)} |0 \rangle ,
\]
that nicely interpolates the spin liquid ground state of the Mott insulator (\( x = 0 \)) and the superconducting doped Mott insulator (\( x \neq 0 \)). Here \( N \) is the number of sites and \( N(1-x) \) is the number of electrons. Gutzwiller projection is defined as,
\[
P_G = \prod_i (1 - n_{i \uparrow} n_{i \downarrow}^{\phi (i)}) .
\]

There was another important suggestion in this paper: two electrons in a given cooper pair will avoid double occupancy and cooper pair function \( \phi (ij) = 0 \) for \( i = j \). This automatically allowed extended-s and higher angular momentum symmetry such as d-wave.

This paper was very special. Superconductivity emerged from a Mott insulator (non-fermi liquid) background. Pairing was not in k-space: superexchange, an intrinsically real space quantum chemical binding phenomenon lead to zero momentum condensation of cooper pairs. This paper[3] has become a classic in quantum condensed matter physics, almost a poem that opened a new door and one that reveals new shades of meaning each time one reads it.

4. BZA theory

BZA followed heels and provided a physically motivated approximation method for the strongly correlated electron problem at hand. It ended up being a beginning of a program. As mentioned earlier, PWA suggested a Gutzwiller projected variational wave functions parameterized by a pair function \( \phi (ij) \). This theory undertook this variational analysis. This is similar to a BCS-Hartree Fock type analysis, but in a restricted Hilbert space containing no double occupancy. That is, one would like to minimize the energy expectation value (or free energy) with respect to the pair function \( \phi (ij) \):
\[
E[\phi] = \langle RVB; \phi | P_G (H_s + H_t) P_G | RVB; \phi \rangle.
\]
Presence of Gutzwiller projector \( P_G \) makes computation formidable. This theory introduced a physically motivated approximation. The approximation amounts to treating the Gutzwiller projection in a mean field fashion and approximate the above expression by
\[
E[\phi] \approx \langle RVB; \phi | x H_s P_G | RVB; \phi \rangle.
\]
That is, the complicated Gutzwiller projection was

---

approximated by replacing the hopping parameter $t$ by a renormalized parameter $x_t$, since $x$ is the probability that an electron can find a neighboring site empty to which it can hop. In other words we have a renormalized Hamiltonian
\[ \hat{H}_{ij} = x H_i + H_s, \] defined in the full Hilbert space, also containing double occupancies. The rest is very similar to standard BCS theory. Interestingly this paper conjectured that this renormalization prescription should work well beyond about 5% doping, about which we will discuss later.

Within the above mentioned approximation this theory found i) a spin liquid ground state, neutral fermion excitations with a pseudo fermi surface for the Mott insulator and ii) a superconducting ground state with extended-s symmetry for doped Mott insulator.

A key point in BZA is a liberation from the Pauli spin operators, that is traditionally used for analysis of quantum spin systems and go to the constituent electron variables, even for the Mott insulator, by rewriting the Heisenberg part of the Hamiltonian as
\[ H_s = J \sum_{\langle ij \rangle} (S_i \cdot S_j - \frac{1}{4}) = -J \sum_{\langle ij \rangle} b_i^\dagger b_j, \] using the relation, $S_i = \sum_{\alpha, \beta} c_i^{\alpha \dagger} c_i^{\beta \dagger} c_i^\beta c_i^\alpha$, where $\tau$ is the Pauli spin matrix. Further $b_i^\dagger = \frac{1}{\sqrt{2}} (c_i^{\uparrow \dagger} c_i^{\downarrow \dagger} - c_i^{\downarrow \dagger} c_i^{\uparrow \dagger})$ is the bond singlet and (or in the present case) neutral cooper pair operator. In the electron representation the Heisenberg Hamiltonian has a simple meaning. The spin-spin coupling encourages bond singlets, because it is minus of the bond singlet number operator $b_{ij}^\dagger b_{ij}$. The non-trivial character of the lattice problem arises from the fact that the bond singlet number operators do not commute, if they share one common site. We [61] showed recently a very useful commutation relation,
\[ [b_i^\dagger b_j^\dagger b_k b_j, b_i^\dagger b_k^\dagger b_j^\dagger b_i] = S_i \cdot (S_j \times S_k). \] It has a deep meaning that singlet resonance or delocalization involves an unavoidable spin chirality fluctuation.

In k-space the cooper pair scattering term arising from superexchange has the following form:
\[ H_{pair} = -J \sum_{k,k'} \gamma (\mathbf{k} - \mathbf{k'}) c_{-k}^\dagger c_{k'}^\dagger c_{k'} c_{-k} \] with the pair potential having the form, $\gamma (\mathbf{k} - \mathbf{k'}) = \{\cos(k_x - k_x') + \cos(k_y - k_y')\}$. It should be noted that the pair potential is attractive, for small momentum transfer $(\mathbf{k} - \mathbf{k'})$, changes sign and becomes repulsive for large momentum transfer $-(\pi, \pi)$, manifestly suggesting a $d_\sigma^\pm \cdot \gamma^\pm$-wave rather than extended-s wave as a low energy mean field solution. For a reason that will be elaborated later, we were extremely satisfied with extended-s wave mean field solution.

It then employed a Bogoliubov-Hartree-Fock factorization and identified nearest neighbor self consistent parameters:
\[ \Delta = \sum_k (\cos k_x + \cos k_y)(c_k^\dagger c_{-k}^\dagger) \] and
\[ p = \sum_{k\sigma} (\cos k_x + \cos k_y)(c_{k\sigma}^\dagger c_{-k\sigma}) \]
(15)
The first one $\Delta$ is the usual anomalous superconducting amplitude. The second one $p$ is somewhat unconventional, it is a kinetic energy or hopping term, a ‘Hartree-Fock Vector Potential’, generated by superexchange process. This unusual Hartree-Fock factorization term introduced in this paper played crucial role in later developments, such as gauge theory and Affleck-Marston’s flux phase[21].

4.1 Mott insulator
Let us first consider the case of zero doping, $x = 0$, the Mott insulator. The simplest self consistent solution was found to be $\Delta = 1$ and $p = 0$. This resulted in a quasi particle Hamiltonian for neutral fermions, $\alpha \ 's$:
\[ H_{MF} = -J \sum_{k\sigma} (\cos k_x + \cos k_y)(\alpha^\dagger_{k\sigma} \alpha_{k\sigma}) \]
(16)
The pseudo fermi surface for the neutral fermions is given by the expression $|\cos k_x + \cos k_y| = 0$. Further, the anomalous pairing leads to a remarkable result for ground state occupancy
\[ n_{k\sigma} = \langle \alpha_{k\sigma}^\dagger \alpha_{k\sigma} \rangle = 1. \] (17)
Even though neutral fermion excitations have a pseudo fermi surface, there is no momentum space discontinuity for the constituent electrons. In this sense this spin liquid ground state of the Mott insulator is far removed from any standard fermi liquid state. The ground state suggested by this RVB mean field theory is the Gutzwiller projected spin liquid state:
\[ |2D RVB\rangle = \prod_k \left( u_k + u_k c_{k\uparrow}^\dagger c_{-k\downarrow}^\dagger \right) |0\rangle, \] (18)
with $u_k = \pm 1$ inside and outside the pseudo fermi surface respectively. Emergence of neutral fermions with a pseudo fermi surface, in a many body theory for quantum spins, was a great excitement at that time. It was radically different from bosonic spin wave excitations in ordered antiferromagnets.

This paper also pointed out that in the Mott insulator, neutral fermion quasi particles are meaningful only when they are created as ‘particle-hole’ pairs $P_G \alpha_{q\sigma}^\dagger \alpha_{q'\sigma} \prod_k (u_k + u_k c_{k\uparrow}^\dagger c_{-k\downarrow}^\dagger) |0\rangle$, with q and q' defined on opposite side of the fermi surface. When they are on the same side of the fermi surface we end up creating charged fermions, which are not part of the low energy excitation spectrum of the Mott insulator. This implied that Brillouin Zone of neutral fermions are only half of the full BZ, very much like the BZ of spinons in...
the case of 1D Heisenberg spin-$\frac{1}{2}$ antiferromagnet.

4.2 RVB superconductor

The mean field analysis was then performed for the doped Mott insulator, $x \neq 0$. In addition to the superexchange term it had the renormalized kinetic energy term $xH_{\text{ex}}$ (equation 11). The problem at this level becomes very much like a standard BCS analysis, with a renormalized band width and nearest neighbor cooper pairing of strength $J$. Thus superexchange becomes the glue.

In addition to the anomalous average $\Delta \neq 0$ (unlike the case of Mott insulator) it also found $p \neq 0$. It is a renormalization of kinetic energy from superexchange term. The overall superconducting solution corresponds to a spin singlet superconducting state with extended-s symmetry.

The mean field solution suggested superconductivity (ODLOR) for any filling. However, at half filling, ODLOR is destroyed by a complete suppression of low energy charge fluctuations, implemented by Gutzwiller projection. That is, at half filling the mean field superconducting state turns into a neutral spin liquid state upon elimination of charge fluctuations. The mean field solution suggested superconductivity (ODLOR) for any filling. However, at half filling, ODLOR is destroyed by a complete suppression of low energy charge fluctuations, implemented by Gutzwiller projection. That is, at half filling the mean field superconducting state turns into a neutral spin liquid state upon elimination of charge fluctuations.

It was pointed out that the mean field transition temperature obtained by this analysis,

$$k_B T_c \sim J,$$

a fraction of the superexchange $J$, is the cross over temperature at which ‘preformed spin singlet pairs’ are beginning to appear in the system. In current terminology this temperature scale is the ‘spin gap’ scale, below which spins are progressively getting paired in a cooperative fashion. These singlet pairs start transporting charge and compete with single electron transport. Thus the mean field temperature provides some kind of umbrella below which the charged valence bonds can undergo BEC type of condensation on their own, making use of their light mass and small density. For small doping the actual superconducting transition temperature will be bounded by the mean field $T_c$.

As doping $x$ increases, the effect of superexchange is decreasing and at the same time a fermi sea is being built, because of increase in electron delocalization. Thus we have some kind of fermi sea with superexchange as the glue. So the $T_c$ predicted by mean field theory will become close to the superconducting $T_c$. This is shown in figure 2, which reproduces the BZA mean field phase diagram. Beyond the dashed line, mean field results for superconducting $T_c$ starts making sense. It is interesting to see that this is close to optimal doping, that was discovered in experiments months later.

At small doping superconductivity was viewed as a condensation of a fraction $x$ of valence bond bosons that are charged and gave a BEC type of expression of $T_c$ for small doping:

$$k_B T_c \sim \frac{\pi \hbar^2}{m^*} \left( \frac{x}{2.61 \nu_0} \right)^2.$$  \hspace{1cm} (20)

Here $m^*$ is the effective mass of the charged valence bond and $\nu_0$ is the volume occupied by each Cu cell.

What is remarkable about this formula is that the superconducting $T_c$ has a strong and explicit dependence only on $t$ and $x$. It does not have any explicit dependence on $J$ or the Hubbard $U$. The large $U$ has done its job through superexchange, of preparing spin singlets at a sufficiently high temperatures. When BEC takes place below spin gap scale $k_B T_c$, spin singlet correlation is maximal, and it is a coherent charge fluid, without much spin activity at low energies. This formula was modified, to a more appropriate Kosterlitz-Thouless type formula in 2D, in a subsequent paper [6] by with Anderson, Hsu and Zou, as

$$k_B T_c \sim \frac{2\pi \hbar^2}{m^*} (x - x_c).$$  \hspace{1cm} (21)

Here $x_c$ is some critical doping needed to overcome disorder and begin superconductivity; this expression was taken from a similar expression for superfluidity of $^3$He in vicor glass. At very high doping Mott insulator turns into a (disturbed) fermi sea. Superexchange becomes less relevant, as electrons are less localized because of decreasing correlations. This mean field theory showed a sharp decrease of the mean field $T_c$ beyond an optimal doping. Synthesizing various ideas and the BZA mean field solutions, a phase diagram was suggested shortly, in the same paper [6]. This phase diagram, shown in figure 3, was also a prediction of BZA theory. The experimental phase diagram that was established later over years has a striking resemblance to this prediction.

This idea of bose condensation of charge valence bonds was given a sharper expression with important consequences, as a holon (soliton) condensation by Kivelson, Rokhsar and Sethna [16] shortly.

The importance of quantum phase fluctuations in a condensate of preformed pairs was emphasized in the BZA paper; these ideas predictions which predated detailed experiments, have matured into notions such as phase fluctuation dominated bad metal phase emery Kivelson and vortex liquid phase [63], with help from a variety of experiments performed after 1987. This basic ideas from RVB theory was used in an important paper by Emery and Kivelson [62] to talk about quantitative comparison of superconducting $T_c$ with experimentally measurable quantities, such as superfluid stiffness, using a phase fluctuation dominated scenario. We will discuss this later.
This phase diagram, drawn in March 1987, was based on a microscopic calculation plus some conjecture about validity of mean field theory at higher dopings. Surprisingly, the conjectured region of validity of mean field theory (beyond dashed line) very nearly corresponds to optimal doping of \( \sim 15\% \) and beyond, that was experimentally confirmed later.

It is also worth emphasizing that BZA paper constitutes an unequivocal prediction of the spin pseudo gap phenomenon, long before it was noticed experimentally.

Even though mean field theory was in agreement with experiments in giving high \( T_c \) superconductivity at optimal doping, an important question was whether the mean field superconductivity will survive quantum fluctuations arising from double occupancy constraint. This paper conjectured that when the doping is above \( \approx 5\% \) the fluctuation correction arising from the double occupancy constant should not matter very much. However it was necessary to validate this in an acceptable fashion either using existing many body theory or something new.

5. Gauge theory

After BZA theory one of the urgent jobs was to give mathematical expression to the increasing phase fluctuations of Cooper pairs, as one approaches the Mott insulator by decreasing the doping. It also amounts to finding how to express mathematically difference between a Mott insulator and doped Mott insulator. The gauge theory paper[5] undertook this study from a very different perspective. It offered a new approach, which distinguished Mott insulator and doped Mott insulator and enabled a systematic study of Mott insulator based quantum fluctuations on superconductivity. This began a new activity of gauge theory approach to strongly correlated electrons systems, and in particularly cuprate superconductors. Some key ideas from lattice gauge theory were very effectively used to understand the strong correlation problems in Mott insulators and doped Mott insulators.

This theory observed that the low energy Hamiltonian of Mott insulator has a local U(1) gauge symmetry, when expressed in terms of the underlying electron variables. This is manifest in the electron representation (eq. 5). A local (site dependent) gauge transformation

\[
 c_i^\dagger \rightarrow e^{i\delta} c_i^\dagger ,
\]

leaves the spin Hamiltonian invariant. Because, \( b_{ij}^\dagger \) transforms as

\[
 b_{ij}^\dagger \rightarrow e^{i\delta} b_{ij}^\dagger e^{i\delta} ,
\]

and leaves superexchange Hamiltonian (equation 5) \(-J\sum_{\langle ij \rangle} b_{ij}^\dagger b_{ij} \) invariant. An important consequence of this is a possibility of an emergent U(1) dynamical gauge field on the links. This link gauge field is a dynamically fluctuating complex field, \( \Delta_{ij}(t) \), connecting neighboring sites \( ij \). Around the same time, while studying Anderson lattice and heavy fermion problems, Noga[64] introduced such dynamically generated link variables. This insight was very useful for us and we used this effectively in our Mott insulator and doped Mott insulator problem.

The dynamically generated field \( \Delta_{ij} \) was shown in path integral treatment of the problem, using a Hubbard-Stratanovic method, which reduces a quartic two body interaction term to a quadratic interaction term with dynamically fluctuating pair field \( \Delta_{ij}(t) \). Path integral expression for the partition function of the t-J model is:
can approximate the hard variable, \(|\Delta_{ij} \approx |\Delta_0|\) and \(\Delta_y \approx |\Delta_0| e^{\theta_y / y}\). In terms of the phase variable the U(1) action has the form:

\[
S_{\text{Mott}} \approx c |\Delta_0|^4 \sum_{ijkl} \cos(\theta_{ij} - \theta_{jk} + \theta_{kl} - \theta_{li})
\]

This paper summarized results of an analysis, using Villain approximation, and a plaquette integer variable (similar to vorticity in XY model in 2D) was discussed. This integer plaquette variable was called ‘magnetic charges’, using analogy to U(1) lattice gauge theory in 2+1 dimensions. These magnetic charges were identified as key ‘topological excitations’ that will describe evolution of spin liquid state as a function of temperature. The magnetic charges or vorticity, is a novel topological excitation that arises in a disordered spin liquid state in 2D, the very first one as far as the authors knew. Kivelson-Rokhsar-Sethna’s holon or spinon was shown to arise when \(\Delta_{ij} = 0\), when they are located at the origin.

It was further suggested that as the gauge field is dynamically generated, by interacting fermions, the magnetic charges might induce fermions, through a possible topological term. This will be a ‘neutral fermion’ (spinon) excitation. In the modern language it will be called a fermion-flux composite. Very soon Dzyaloshinski, Wiegman and Polyovikov [55] suggested Hopf term as a topological term. It suggested a possibility of statistics transmutation and a debate started about existence of Hopf term in 2D spin-\(\frac{1}{2}\) Heisenberg antiferromagnet. In parallel, Marston [66] and also Zou [67] suggested a Chern-Simon term in the U(1) gauge theory. Thus the gauge theory paper planted seed for the discussion of Chern-Simons field theory to describe 2D quantum spin systems.

Soon the magnetic charge was called by a more appropriate name, ‘magnetic flux’ and Affleck and Marson found the \(\pi\)-flux RVB mean field solution in the BZA theory. This state respects parity and time reversal, as \(+\pi\) and \(-\pi\) can not be distinguished quantum mechanically (Bohm-Aharonov effect). A chiral spin liquid state that was suggested by Kalmayer and Laughlin [57], in a triangular lattice antiferromagnet was shown to be related to an RVB mean field solution with condensed \(\pi\) flux, by Feng and Lee [68]. In more recent works the magnetic flux was christened as ‘visons’ in the works of Senthil and Fisher [30]. Very recent work by GB [69], following an early work of us with Anderson, John, Doucot and Liang [70], finds that the well known skyrmion solution of 2D Heisenberg antiferromagnet represents two unbound spinons that carry quarter magnetic flux each, and showing an important result that spinons are deconfined semions, but above an energy gap.

The magnetic charge or flux, that came in a natural fashion in the RVB theory was described by Wen-
Wilezck-Zee [26] in terms of spin chirality variables expressed, in terms of Pauli spin operators as:

$$\forall e^{igA(r)d} \sim S_j \times (S_j \times S_k)$$  (30)

Another important consequence of U(1) gauge field description in a lattice was an application of Elitzur's theorem [71]. Elitzur theorem states that in a pure lattice gauge theory (without matter) with local gauge invariance, the local gauge symmetry can not be spontaneously broken. Thus Elitzur theorem automatically precludes spontaneous symmetry breaking of the U(1) gauge field in the Mott insulating state. It means absence of superconductivity in a Mott insulator. This paper also pointed out possibilities of confined and deconfined phases of U(1) gauge theory, through the area and power law behavior of Wilson loop like loop correlation functions such as

$$W(C) = \langle \prod C_i b_{ij} b_{jk} b_{kl} \ldots b_{pi} \rangle.$$  

In the deconfined phase the neutral fermions carrying spin-$\frac{1}{2}$ moments were suggested to be present as low energy excitations.

Next important question is the consequence of doping and how it will bring about superconductivity in the gauge field description. This paper showed that the doped Mott insulator described by the t-J model does not have local U(1) symmetry of the parent Mott insulator. That is, in the presence of a non zero doping $x \neq 0$, the effective action $S_{eff}[\Delta_j(r)]$ is invariant only under a global U(1) gauge transformation, $\Delta_j \rightarrow e^{i2\theta} \Delta_j$.

We evaluated the effective action, using the same approximation as before and obtained,

$$S = -a_0 \sum_{ijkl} \Delta^*_i \Delta_j \Delta^*_k \Delta_{l} + H.c. + xa_0 \sum_{ijkl} \Delta^*_i \Delta_j \Delta^*_k \Delta_{l} + H.c. +$$

$$+ b \sum_{\{j\}} |\Delta_j|^2 + c \sum_{\{j\}} |\Delta_j|^4. \quad (31)$$

This had a remarkable consequence. As the second term proportional to $x$, the dopant density, removes the local gauge invariance, total action has only a global U(1) gauge symmetry. The first term representing a plaquette resonance of the valence bonds is the memory of the Mott insulator in this approach. An immediate consequence was that Elitzur’s theorem is no more applicable now. In principle superconductivity is possible. Action (eq. 31) is the simplest lattice Ginzburg Landau action for RVB superconductors. The major aspect of RVB appears from the plaquette resonance term, which fights against long range order. During 1988, Nakamura and Matsui [22] used the above lattice action and did a complete numerical evaluation of the partition function (going beyond saddle point approximation) and found reasonable superconducting $T_c$ close to doping. This was an important numerical proof that 2D superconductivity survives gauge field fluctuations at optimal dopings.

Soon after the gauge theory paper, Muller-Hartman’s group [72] calculated the coefficient of the static lattice RVB-GL action, taking care of double occupancy constraint more accurately and obtained a detailed phase diagram in the $x$-$T$ plane.

The effective action found the gauge theory paper, like the BZA method, has the right physics as far as symmetry of the superconducting order parameter is concerned. The coefficient of the ‘gradient term’ in the lattice $xa_0 \sum_{ijkl} \Delta^*_i \Delta_j + H.c.$ had the right sign ($xa_1 > 0$). And minimization of the above action automatically leads to a $d_{x^2-y^2}$ solution, very similar to Kotliar’s $d$-wave solution.

The RVB-GL action above does not have fermions explicitly, as they have been integrated out completely. This is not correct for a $d_{x^2-y^2}$ superconductor as it has nodal fermion quasi particles. So the low energy Bogoliubov quasi particles and their coupling to $\Delta_j$ should be present as part of the action. This is easy to incorporate either phenomenologically or microscopically. Many authors such as, Affleck, Marston, Matsui, Nakamura, Wiegman, Ioffe, Larkin, Patrick Lee, Wilczek, Zee, Nagaosa, Read, Sachdev, Balents, Nayak, Fisher, Senthil, Dung-Hai Lee, Tesanovic, Franz and others have contributed to the elaboration of these fundamental ideas, most of them using continuum action.

However, it is important to point out that it is difficult to incorporate the plaquette term, which keeps the memory of the Mott insulator, in a continuum approximation. To this extent, the RVB-GL theory on a lattice remains unexplored. We find that because of the plaquette term, which distinguishes it from a standard superconductor, many interesting consequences could occur; for example, Andreev bound states at the vortex core and nature of impurity states induced by Zn and Ni substitution at copper site. In a recent work Muthukumar and Weng [73] have developed an RVB-GL theory, starting from a slave fermion approach, and studied the physics of spinon vortices and properties of electromagnetic vortex core.

6. Completing the BZA programme

6.1. $d$-wave Solution in BZA theory

As mentioned earlier, the available experimental data at the beginning of 1987 was not inconsistent with absence of long range magnetic order in the Mott insulating end. Further, in the doped Mott insulator, experiments continued to show a small amount of electronic linear specific heat at low temperatures in the superconducting region. Both these results gave PWA a confidence that the quantum spin liquid with a pseudo fermi surface at the Mott insulator continues to become a superconductor with extended-s symmetry, and retains neutral fermionic excitations with a pseudo fermi surface. Overwhelmed by this confidence we were sailing happily in a pseudo fermi sea.

During this period, intrigued by the structure of BZA...
mean field theory and the gauge theory[5] approach, Affleck and Marston[21] found a π RVB flux mean field solution for the Mott insulator and Kotliar[17] the $d_{x^2-y^2}$ solution for the superconductor, within the BZA approach. Affleck and Marston presented their results as an exact result in a large N limit of a generalized Heisenberg model in 2D.

As mentioned earlier, mean field energy of $d$-wave being lower than extended $s$-wave is seen as follows. In BZA theory, the pair potential, for pair scattering, is given by $-J^\prime (k - k') = -J [\cos (k_x - k_x) + \cos (k_y - k_y)]$. This potential, which is attractive for small momentum transfer $k - k'$, changes sign and becomes repulsive for large momentum transfer $k - k' \approx (\pm \pi, \pm \pi)$. The $d_{x^2-y^2}$ solution, which changes sign as we move along the fermi surface in k-space takes advantage of this and becomes a lower energy state.

Even after Kotliar's solution, there was a reluctance from Princeton group to accept $d$-wave solution. In addition to the then existing phenomenological support for extended-s solution, we were not sure if the BZA $d$-wave solution will continue to have lower energy than extended-s solution, after Gutzwiller projection. Later Gutzwiller projected $d$-wave BCS solution was shown to have lower energy using numerical methods.

The beauty of Affleck-Marson and Kotliar's solution was that both had nodal quasi particles. Various experimental results that followed later demonstrated clearly $d$-wave superconductivity for hole doped cuprates. Needless to say that an unconventional order parameter such as $d$-wave has its own profound consequences for cuprates, as has been seen both in the experimental and theoretical fronts in the last two decades. It is fair to say that RVB theory contains in its bag all these fascinating possibilities and perhaps even more. A recent excitement is with respect to superconductivity in Na$_2$CoO$_2$,yH$_2$O. We have developed an RVB theory for this system[74], where $d$ + id, another unconventional order parameter that violates parity and time reversal symmetry is predicted.

6.2. Improving BZA mean field hamiltonian

As discussed earlier, the hard problem of Gutzwiller projection was replaced by an ansatz in the variational analysis. We replaced the hopping parameter $t$ by $tx$. This tells us that an electron can hop to a neighboring site only when it is empty. The probability of it being empty is $x$, the doping density. This is equivalent to replacing bare electron mass by a renormalized mass, which was already familiar to us from the work of Brinkman and Rice in the context of Mott insulator to metal transition in Hubbard model at half filling.

While evaluating expectation values involving Gutzwiller projection, an approximate method that takes care of some incoherent aspects of projection, was developed by Gutzwiller, in his earlier study of Hubbard model. It involved certain combinatorics. This method was already successfully used by Rice, Joynt, Shiba, Ogatta, Vollhardt, Anderson and others in dealing with issues of heavy fermions and also Hubbard modeling of solid $^3$He. This method was adapted by Zhang, Gros, Rice and Shiba[20] to improve the BZA renormalization process. Their improvement is schematically shown below.

\[
P_G(H_i + H_s)P_G \xrightarrow{BZA} (x H_i + H_s) \xrightarrow{ZGRS} \]

with doping dependent renormalization parameters $g_t = \frac{2x}{1+x^2}$ and $g_s = \frac{4}{(1+x)^2}$. But for the two new renormalized parameters the rest of the self consistent theory was identical to BZA theory. Further, physical correlation functions such as anomalous amplitudes $\langle h_i \rangle$, got an appropriate renormalization factor $g_t$ times mean field amplitude :

\[
\langle h_i \rangle \rightarrow g_t \langle h_i \rangle_0 .
\]

This is in spirit similar to BZA theory, where it is stated that fraction of singlet bonds that are charged are $x$ and use this to calculate superconducting $T_c$. It should be also pointed out that the renormalization parameters $g_t$ and $g_s$ are also not variational parameters, very much like in BZA theory. Here also one gets a gap equation for the order parameter $\Delta$ and $p$, which can be solved self consistently. The merit of the improvement suggested by ZGRS is that the results obtained by a mean field analysis is quantitatively more accurate. This is elaborated in the Plain Vanila paper as well as more recent works of Zhang et al and Muthukumar-Gros et al.

Generalization of the above BZA program to finite temperature has problems. This problem is related to variational states that are orthogonal before Gutzwiller projection becoming non-orthogonal after Gutzwiller projection and decrease in density of relevant Hilbert space introduced by double occupancy constraint. Anderson[49] has recently offered an analysis, where he introduces the notion of ‘spin-charge locking’ and introduces a generalized BCS type of formalism, where separate Anderson-Nambu spinors are introduced to take care of neutral spin-pairing and electron pairing. At very high temperatures they are decoupled and in the superconducting state they are locked. Spin-gap phase represents a progressive locking.

6.3. Holon condensation & slave boson theory - a support for BZA program

Soon after Anderson’s paper and BZA theory, an insightful paper by Kivelson, Rokhsar and Sethna[16] offered a theory where a doped charge enters as holon, a spin zero soliton with charge +e. They act like bosons andbose condense leading to superconductivity. It seemed to express, in a formally correct fashion, Anderson and BZA’s result of viewing the charged
valence bond as a boson and their bose condensation. 
Zou and Anderson[7] adapted the slave particle method, 
developed earlier by Barnes, Coleman, Read, Newns, 
Kotliar and Ruckenstein, to the t-J model. This began a 
series of investigations starting with the work of Kotliar-
Liu, gauge theory by Wiegman[23] and the present 
author[24], and detailed mean field analysis by 
Fukuyama[19] and collaborators and several other 
investigations.

The advantage of slave particle method over the 
variational approach is that one can introduce 
dynamically generated gauge fields and go beyond mean 
field theories, without constrained by variational RVB 
states and also address finite temperature problems. 
However they are technically hard, as it is clear in the 
works of many authors that followed. BZA mean field 
theory seems to capture the essence of superconductivity 
phenomena in the t-J model.

In some limit the slave boson analysis gives the same 
result as the improved BZA Hamiltonian by Zhang et al. 
During this development, we also showed[6] that the 
holon condensation is not actually a charge 2e rather 
charge e condensation in view of the double occupancy 
constraint. In other words, electron pairs get effectively 
delocalized into a zero momentum condensed state. Or 
holon is book keeping device for a correlated fluctuation 
and delocalization of charged valence bonds, as far as 
superconductivity is concerned.

6.4. Lurking dangers outside optimal doping

As RVB theory was being developed, there was a 
conscious effort to focus on region around optimal 
doping. RVB superconductivity is at its best and one can 
hope to understand it better here, than elsewhere. In fact, 
t-J model is a reasonable model for real cuprates, when 
we have either an isolated hole in a Mott insulator or a 
finite density of holes at optimal doping! Any thing in 
between is complicated because of unscreened long 
rage coulomb interactions among charge careers, strong 
coupling to phonons and disorder effects from off plane 
dopants. It could easily lead to nano scale phase 
separation into Mott insulating and optimally doped 
regions, self trapping etc.

In reality it turned out to be even more complicated. 
A doped Mott insulator also supports other quasi or 
seuo long range orders such as fluctuating charge and 
spin orders and chiral orders, involving circulating spin 
currsents and charge currents. Interactions not contained 
in the t-J model, seem to encourage these competing 
orders, outside the superconducting dome. They are 
fascinating quantum and classical condensed matter 
problems. However, they are not crucial in our foremost 
goal of understanding high Tc superconductivity deeply. 
There are good phenomenological and theoretical 
evidences that they are not the root cause of high Tc 
superconductivity. In fact, they are competitors[81].

The same is true of the so called pseudo gap phase, 
outside the dome. Experimental evidences point to 
presence of enhanced correlations corresponding to the 
cometing order.

There is a clear indication that the physics and 
interactions contained in the t-J model 2D is alone able 
to support high Tc superconductivity, without need for an 
external help or a catalytic agent.

7. Mean field theory works remarkably well at 
optimal doping

RVB mean field theory and gauge theory approach, 
predicted a robust superconducting state at optimal 
doping with a large Tc and supported, Anderson’s 
proposal. These papers also pointed out that in the 
superconducting region, mean delocalization energy per 
particle (~ xt) and energy of superexchange (J) are 
comparable. The superconducting condensation energy 
is a finite fraction of J or xt. Now we know that 
J/kB~1500K for cuprates and superconducting 
condensation energy is large and so are superconducting 
Tc’s. This puts cuprates on a different region in the 
Uemura plot. In fact, Uemura plot itself was inspired by 
RVB type of idea of bose condensation of charged 
valence bond in cuprates.

Fortunately for the above theories, new cuprate 
family members were discovered, where 
superconducting Tc’s soared to new heights. The Hg and 
TI based single layer superconductors reached a Tc in 
the range of 95 K. At optimal doping, Tc is large compared 
to its one layer counterpart LSCO or one layer BISCO 
material. I have argued elsewhere, that a single layer 
material has a large intrinsic superconducting Tc 
~120K. Competing orders (charge and spin order 
tendencies, often helped by octahedral rotation or 
distortions) steal away the superconducting condensation 
energy, making superconducting Tc among one layer 
materials to swing from 5 K to 95 K at optimal doping.

The highest Tc is in the TI based cuprates, where Tc is 
as large as 163 K, under large external pressures. These 
are remarkable experimental support to the BZA and 
gauge theory approximations.

Several theoretical attempts readily show enhanced 
singlet correlations in the ground state, a prerequisite 
for long-range singlet superconductivity. Variational Monte 
carlo analysis of RVB superconducting wave functions 
have given useful results, where quantitative 
comparisons have been made with some experimental 
quantities. Over years quantum Monte carlo methods 
have given encouraging results. Other approaches, such 
as real space as well as k-space cluster DMFT have 
given very meaningful results, consistent with BZA 
RVB mean field theory.

One of the best support for BZA program was 
provided by a semi phenomenological theory due to 
Emery and Kivelson[62], which focused on 
superconducting transition temperature. Kivelson and 
Emery assumed, consistent with RVB theory and the 
existing phenomenology that superconducting 
phenomena at low doping is dominated by phase 
fluctuations rather than amplitude fluctuations. This 
leads to a simple expression for superconducting Tc in
terms of measurable quantities. In particular energy
associated with spatial variation of phase is expressed as:
\[ H = \frac{\hbar^2 n_s(0)}{8m^*} \left( \nabla \phi(t) \right)^2 dt. \] (34)

Here \( m^* \) is the effective mass of cooper pair and \( n_s(0) \) is
the superfluid density at zero temperatures. Then one can
use the standard KT formula to get an expression for superconducting \( T_c \) as
\[ k_B T_c = \frac{\pi \hbar^2 n_s(0)}{8m^*}. \] (35)

This expression is remarkably similar to the expression
given in BZA paper and the later paper with Zou and
Hsu (eqs. 20 and 21). Emery and Kivelson went further and made
detailed comparison with existing phenomenology, including how \( T_c \) increases with inter
layer coupling etc. The remarkable result is that, as in the
BZA result, here also large \( U \) or \( J \) does not explicitly
appear in the final result for \( T_c \). Superexchange, a
consequence of large \( U \), simply provides a large energy
scale and an umbrella below which fairly stable singlets
can delocalize and produce a superconducting state,
along the lines of BCS. As thermally produced nodal
quasi particles will interfere with superconductivity, in a
way different from the fully gapped superconductors,
certain corrections were necessary to the above analysis,
as indicated in reference[33].

Even though no rigorous theorem exists proving existence
of a finite \( T_c \) superconductivity in large \( U \) repulsive Hubbard model or \( t-J \) model in 2D, it is
increasingly becoming clear that such a theorem is likely
to exist. However, one should remember that spin-
\( \frac{1}{2} \) systems are notoriously hard. For example, a rigorous
demonstration of long range antiferromagnetic order, in
the undoped 2D square lattice Heisenberg
antiferromagnet does not exist even now. Will doping
make it any simpler?

As mentioned earlier, in the heat of developments
during the beginning of 1987, a phase diagram was
conjectured in the paper by Anderson, Hsu, Zou and
the present author, based on BZA theory (Figure 3). This
phase diagram was conjectured well before experimental
phase diagram emerged. It is interesting that the
experimental phase diagram had an excellent overall
form as conjectured by the theory. This again indicates
that the fluctuation effects do not change the qualitative
prediction of the mean field theory.

BZA paper also pointed out that ‘... in the low doping
concentration limit (\( x << 1 \)) phase fluctuations play an
important role and the mean field theory fails. At this
limit, \( T_c \) and gap are governed by the large phase
fluctuations.... But for large enough \( x (> 5%) \) we expect
that the mean field theory works.’ The main reason for
the conjecture was that, in order to be able to construct a
phase coherent superconducting state, two most
important requirements are i) well developed short range
singlet correlations and ii) finite long wavelength charge
compressibility. Singlet correlation is there in plenty in
the doped Mott insulator, because super exchange
continues to be present for a range of doping. A doping of
5% gives sufficient delocalization energy to escape
localization effects due to disorder or hole-hole
electrostatic interaction and attain a finite charge
compressibility.

Spin-1 collective mode at \((\pi, \pi)\) first seen in neutron
scattering[75], is one of the key unconventional feature
of cuprate superconductivity. As far as I know no such
spin-1 collective mode is seen in any conventional
superconductor. Moreover, the frequency of this mode
scales linearly with superconducting \( T_c \). In fact, when \( T_c \)
becomes zero this mode becomes the Goldstone mode of
the antiferromagnetic order, that is supported by a Mott
insulator through superexchange. Thus spin-1 collective
mode is a memory of the Mott insulator. It is a simple
manifestation of the tightly bound bond singlets that
makeup the superconducting state: these singlets are
softer at \((\pi, \pi)\) in k-space. This reveals a dynamic
antiferromagnetic correlation at \((\pi, \pi)\), at energy scales
large compared to the superconducting energy scale. The
simplest theory that explains the spin-1 collective mode
at \((\pi, \pi)\), in a natural fashion at \((\pi, \pi)\) is an RPA
collective mode analysis built on a BZA type of \( d \)-wave
mean field background, within a \( t-J \) model. This is
another support for the mean field theory.

In a recent paper Anderson and collaborators[48]
have made comparison of the physical properties
calculated within ZGRS approach, variational Monte-
Carlo analysis and experimental results. The agreement
between the three are very good, underscoring the
validity of the original BZA approach and the
assumptions therein.

Another reason why a simple BCS type of theory
works well at optimal doping is the following. For zero
and very small doping the strongly correlated electronic
system has strongly localized electrons and there is no
resemblance of the ground state to a metallic fermi sea.
For very high doping we clearly have a degenerate fermi
gas; at these heavy dopings superexchange does not take
place, as electrons have a large mean velocity and do not
have time for superexchange interaction with a neighbor
in real space. At optimal dopings a reasonable fermi sea
is formed at the same time superexchange also survives.
It is this combination which makes the situation very
similar to a BCS theory with superexchange being the
glue. This is the reason BZA renormalized Hamiltonian
and the improved version by ZGRS work well.

7. Is spin fluctuation a glue?
The BZA program that was initiated in 1987 and got
completed shortly, is capable of answering many
questions in the superconducting region. Surprisingly
such work began only recently. Partly because, we were
either ignorant or ignored key old developments. Too
many questions, not necessarily related to the major
debate, arose from a wealth of experimental results. Being a complex system, cause and effects get mixed up sometimes. We will use the spin fluctuation scenario to illustrate our point.

Historically, Hirsch’s numerical analysis of the single bond Hubbard model, brought out the beautiful possibility of an extended-s wave superconducting correlation. This and other developments started focusing on this phenomena in terms of diagrammatics and exchange of spin fluctuation bubbles.

Let us look at experimental facts. At optimal doping, a spin-1 resonance emerges at \((\pi, \pi)\), as a sharp mode, but only in the superconducting state. In the normal state it becomes very broad and disappears. This is a collective mode, characteristic of the RVB superconducting state. Further, the energy of this mode scales linearly with superconducting \(T_c\). Formally, as the superconducting \(T_c\) vanishes, this mode becomes a spin wave or Goldstone mode. Further, in addition to the spin-1 resonance there is a broad background of spin fluctuation activities, as seen in \(S(q)\).

RVB theory takes the point of view that spin fluctuation contribution to \(S(q)\) around \((\pi, \pi)\) is a result of a built up of singlet correlation through superexchange processes. These fluctuations that occur in a broad range in momentum and energy space are far from any coherent modes. Instead of talking about these dissipative spectrum of spin fluctuation activities, RVB theory directly focuses on superexchange \(J\) and treats it as a glue. The only coherent mode is the spin-1 resonance. As it has been pointed out, it has a very small spectral weight and further it occurs only below \(T_c\). So it can not be a glue either.

All these phenomena are manifest in diagrammatic spin fluctuation calculations. Electron has a strong frequency and momentum dependent and large normal and anomalous self energies. They depend on each other self consistently. The large normal part of the self energy makes the quasi particles spectral function very broad, consistent with ARPES experiments. But this approach misses the build up of singlet correlations, as a result there is no way we can even approach under doped region, leave alone the Mott insulator region by this approach. There is no natural and simple way of getting superfluid density being proportional to doping at small \(x\). There is a missing logic. While one may get some satisfactory answers, a complete picture, a claimed strength of RVB theory is absent.

8. Conclusion

In condensed matter physics we attempt to synthesize new laws, notions and introduce new reference states or phases in demystifying properties of complex materials. There are several idealized reference states for describing a variety of quantum phenomena in solids: free electron gas, ideal Bose gas, harmonic phonons, fermi liquids, Luttinger liquids, BCS paired fermi sea, etc. The wealth of quantum condensed matter phenomena force us to introduce new reference states occasionally.

PWA’s RVB proposal in 1987 and subsequent developments in the last 20 years illustrates a struggle to introduce Mott insulator as a reference phase to describe the unusual high \(T_c\) superconductivity and a variety of related anomalies [9] in the family of cuprates. From superconductivity point of view, it is a serious attempt to find an alternative to phonon mediated superconductivity, compelled by experiments.

Looking back, it has been a worthwhile struggle, and RVB theory has silently entered the subconscious of the condensed matter mind. \(La_2CuO_4\) has become a text book Mott insulator. A one band model, with strong correlation, namely \(t-J\) or large \(U\) Hubbard model is accepted as a minimal model to describe low energy physics of cuprates. Deep consequences of projection in these models are also getting accepted, but slowly. The \(U(1)\) RVB gauge field theory [5] has been nurtured and developed by several authors in commendable ways. Old ideas from RVB are being rediscovered. The pseudofermi surface and neutral fermions suggested PWA [3] and shown to be a possibility in a microscopic theory in BZA, is being realized in certain organic Mott insulator, ET-salts [76]. RVB mechanism is being successfully applied to understand superconductivity in organics [77,78]. A new superconductor \(Na_xCo_2yH_2O\), is likely a long awaited doped spin-\(\frac{1}{2}\) Mott insulator on a triangular lattice [74]. There is a strong indication for RVB superconductivity in boron doped diamond [79], through superexchange effects in an impurity band Mott insulator.

In the field of superconductivity, before cuprates appeared in the scene, one was used to the luxury of a beautiful and powerful BCS theory, that is so useful in understanding majority of elemental superconductors. Formalisms such as the Eliashberg theory, a microscopic approach and other related developments have been extremely helpful in understanding many experimentally measured properties, including tunneling spectra, \(\alpha^2 F(\omega)\) etc., accurately Ginzburg-Landau phenomenological theory gets a microscopic meaning through Nambu-Gorkov formalism. Space and time dependent superconductivity phenomena and quasi particle dynamics is understood through Bogoliubov-de Gennes theories. There are new phenomena that came as prediction after BCS theory: Josephson effects, Andreev reflection etc. All is well with old superconductivity. Once we agree to live with a few parameters of less microscopic origin, even some bad actors such as \(A15\) and Chevrall phase compounds seem to yield to BCS theory.

The situation with cuprates and many new materials, suspected to be RVB superconductors are different. We mentioned about the lurking dangers out side optimal doping from competing phases and extra interactions that could encourage their growth. This makes a theory based on \(t-J\) model of some what limited validity! Much care should be taken to get all the low energy physics
from the t-J model. For example, determination of superconducting \( T_c \) for a given system, say LSCO is fraught with complications in the way we explain below.

In BCS theory we used to worry about isotope shift of a fraction of a degree in \( T_c \). In cuprates, at optimal doping, in one layer materials, the \( T_c \) varies between 5 K to 95 K between Bismuth and Thallium one layer materials. All these materials have very similar normal state properties, such as the coefficient of linear resistivity, modulo some material purity complications. Such a large variation indicates that superconductivity is not alone. There are other factors and competitors that are at work. Single layer superconducting \( T_c \) may even get enhanced by an interlayer pair tunnelling phenomena [8] in bilayer systems, an entirely new additional contribution that owes its origin to anomalous normal state.

So the world of cuprate superconductors are different and complex. First one has to answer some generic questions as accurately as possible for the 2 dimensional t-J model. For example, what is the \( x \) dependence \( T_c \) near optimal doping. What is the maximum \( T_c \) at optimal doping for a range of \( t \) and \( t' \) and \( J \) that is relevant for cuprates. How \( T_c \) gets modified in a bilayer or multilayer system for a given \( t_\perp \).

It is not meaningful to pick up LSCO and try to understand superconducting \( T_c \) from t-J model. We will be tempted to find the correct band parameters \( t, t', J \) and do an accurate RVB mean field theory. It is very clear that what controls the experimentally seen reduced \( T_c \) is some phenomena outside t-J modeling or band structure effects. In fact, in one experiment[80] an epitaxial strain increases the superconducting \( T_c \) of LSCO thin film from 25 to 50 K, without any manifest increase in doping. Simple estimate shows that epitaxial strain can not give sufficient change in \( t' \)'s to cause such a large effect. The fundamental reason seems to be that epitaxial strain is encouraging certain atomic scale lattice distortion that encourages charge order formation consistently.

There is some new physics[81], namely a competing phase, which is stealing away superconducting condensation energy. As BISCO and TI one layer materials are affected in different ways, actual theoretical prediction of ground state gap parameter, will require additional inputs, either phenomenological or microscopic. One of the important question is how easily the Cu-Oxygen octahedron, or pyramid or square planar complex respond and get distorted or rotate in their different environments, to either charge or spin or valence bond localizations and ordering tendencies. Then there will be feed back and growth of competing orders, at the expense of superconductivity.

One of the strategies will be to pick the best superconductor in the single layer family for a deeper understanding of mechanism of superconductivity. From this point of view our first superconductor namely doped \( \text{La}_2\text{CuO}_4 \) is a bad system to study! Superconducting \( T_c \) never goes beyond 30’s at optimal doping. Do we have to abandon two decades of experimental efforts? Perhaps not. Then an important question is why doped \( \text{La}_2\text{CuO}_4 \) or other low \( T_c \) members have never attained their full potential (maximum \( T_c \)) that TI one layer system has reached. These are new questions that has no parallel in conventional superconductors.

At the end it may be possible to accommodate effects of competing orders phenomenologically by modifying \( t', J \) etc. But that might miss important physics. It is important to recognize and treat competing dynamical processes in their own right. This of course makes the problem hard.

So we realize after 20 years of cuprate study that we are in a different situation. The nature of questions asked should be different and method of analysis will be different. Priorities will be different. For example one of the important question will be how to reach the full potential or maximum superconducting \( T_c \) in the one layer family? As we said earlier, the one layer superconducting \( T_c \) can be as large as 95K. However, in multi layers we have a superconducting \( T_c \) of 163 K. Is it a consequence of cooperation from interlayer pair tunnelling phenomena within the multi layers, or some structural rigidity that discourages competing orders, there by making a single layer realize new heights?

We have focused on only one thermodynamic property. We have similar question about the energy of the spin-1 collective mode and a variety of other key physical properties.

There are several important experimental issues in the superconducting state: temperature dependence of order parameter, nodal quasi particle dynamics, as revealed by magnetic resonance studies, \( S(q, \omega) \) from neutron scattering, spectral functions of quasi particles in ARPES, detailed space and energy dependent STM study of local electronic density of states and gap functions, quasi particle interference effects, structure of vortex core, states inside the vortex core, bound states around impurities such as Zn, Ni and their different and unexpected effects as a function of temperature, thermal conductivity anomalies etc.

Suddenly one finds oneself in the midst of a flood of questions and real complications, so different from elemental superconductors. As we mentioned earlier it is a meeting place of quantum magnetism and superconductivity, Mott insulator and fermi sea. Many things other than superconductivity are taking place. It is unfair to say we do not understand high \( T_c \) superconductivity. We understand it too well, so we fear it and tread carefully.

Anomalous normal state phenomena takes us to a different world all together. Experimentally, it is a clear case for a non fermi liquid in 2D. The many body theory we have developed, to address these challenges, are at the beginning stage. PWA has attacked this problem from different angles : i) a non-vanishing phase shift at \( 2k_F \), in the forward scattering spin singlet channel, in
2D Hubbard model ii) tomographic Luttinger liquid, asymptotic Bethe ansatz in 2D iii) Anderson-Khveschekno’s anomalous commutation relations, iv) spin charge decoupling and two relaxation times on the fermi surface v) asymmetry in single particle tunneling arising from the key projection in a t-J model and vi) very recently an orthogonal catastrophe inherent in the projected t-J model etc.

Similarly, in defect free underdoped cuprates superconductivity seems to vanish because of quantum fluctuations or unscreened coulomb interactions, leaving a metallic ground state. This possibility that was suggested earlier [4] with a pseudo fermi surface and later with nodal quasi particles [82]. The one with nodal excitations seems to be gaining experimental support[83] in very pure YBCO. It will be a pristine RVB state, a reference non fermi liquid state, that has not yielded to instabilities such as charge order or spin order or superconductivity. P and T violating metallic ground states are likely to exist in organics and in cobalt oxide systems [74], near the Mott insulator end.

So it is humbling to see the kind of problems and also richness that Bednorz and Müllers discovery and Anderson’s RVB proposal has created in the world of superconductivity and strongly correlated electronic systems. At the same time it is heartening to see that BZA and related papers have answered the primary question of existence of high temperature superconductivity in cuprates in a microscopic theory, rather satisfactorily, and is ready to answer several old and new questions.

Acknowledgement
I thank P. W. Anderson for a continuing collaboration and for insight ful and critical discussions. I thank M. Muthukumar (Amherst) and V. N. Muthukumar (CUNY) for very useful comments on the manuscript.
